^{35}Si β^- decay (0.78 s) 1988DuZS,1986Du07,1988DuZT

Parent: ^{35}Si: E=0; $J^\pi=7/2^-$; $T_{1/2}$=0.78 s *12*; Q(β^-)=10470 *40*; %β^- decay=100

^{35}Si-J^π,$T_{1/2}$: From Adopted Levels of ^{35}Si.

^{35}Si-Q(β^-): From 2021Wa16.

1988DuZS, 1986Du07, 1988DuZT: ^{35}Si produced by fragmentation of ^{40}Ar beam of 2x10^{11} particles/s at 60 MeV/nucleon on a 190 mg/cm^2 Be target at GANIL. Decay observed with a 1 mm thick plastic scintillator and a 174 cm^3 intrinsic Ge detector (1.2% absolute efficiency at 1.33 MeV). Measured $\beta\gamma$(t), Eγ, Iγ. Deduced levels, J, π, parent $T_{1/2}$.

1987Wa10: shell-model calculations for ^{35}Si β^- decay scheme, ^{35}P levels, decay branching ratios, log *ft*, and Gamow-Teller transition strengths.

2007Ne14: measured ^{35}Si ground state g-factor using the β-NMR method.

The decay scheme is considered incomplete due to a large gap of about 4.9 MeV between the highest observed level at E=5561 and Q(β^-) value=10470 *40* (2021Wa16). There may be missing transitions from unobserved levels in the gap.

† β-feeding from γ-ray intensity balance at each level. Quoted Iβ^- values are considered upper limits due to the incomplete decay scheme, and the associated log *ft* values are considered lower limits.

‡ Absolute intensity per 100 decays.

γ(^{35}P)

Iγ normalization: From Σ%I(γ to g.s.)=100. The deduced normalization factor of 0.27 should be considered an upper limit due to potential missing γ transitions from unobserved levels in the gap to the ground state.
